Abstract

The idea of the universe with a mirror sector having all particles and forces identical to those in the familiar sector has been proposed in the context of neutrino physics as well as superstring theories. Assuming that all the quark and charged lepton masses in the mirror universe are scaled by a common factor, ζ , as is required in one interpretation of the neutrino data, we investigate domains of the parameter ζ where physical conditions are favorable for cooling in the age of the universe that can lead to the formation of compact structures given the initial condition $\Omega_B \simeq \Omega_{\tilde{B}}$ ($\tilde{B}$ denoting the mirror baryon). In particular we ask whether there is a region in

ζ -space for which primordial Jeans mass mirror clouds cannot cool in the present age of the universe. We find that, for most of the area of interest in the parameter space, atomic hyperfine structure cooling is effective in a time period short compared to the age of the universe but long compared to the free fall time for globular cluster-sized objects expected on the basis of simple Jeans length analysis.

I. Introduction:

The idea that our present universe may have a mirror partner evolving with identical matter and force content has been invoked for various reasons from time to time during the past thirty years. The continuing interest in the phenomenology of such models was revived in the late eighties by the observation that the superstring theories (Green et al. 1986) lead naturally to such a picture where the known particles are accompanied by a duplicate set, with identical properties, but in which the two sets have little or no interaction except for that of gravitation (see for example Khlopov et al 1991; Kolb, Turner and Seckel 1985; Hodges 1993 and references therein). Most recently this idea has emerged from attempts to understand the experimental observations relating to neutrino oscillations (Berezhiani and Mohapatra 1995; Foot and Volkas 1995; Berezhiani et al. 1995) such as the solar and atmospheric neutrino deficits (Winter 1995) as well as indications from the LSND (Athanasopoulos et al. 1995; Hill 1995) data. The idea is particularly attractive in any model that requires an ultralight sterile neutrino to fit observations. Our focus in this paper will be on the class of models advocated in Berezhiani and Mohapatra (1995) and Berezhiani, Mohapatra and Dolgov (1995) where solar neutrino data require that the weak scale of the mirror universe be higher than that of the standard model. This model (the weak scale asymmetric mirror model, WSAM) has features of particular astrophysical interest: no mirror element, except hydrogen, is stable; the mirror proton mass is similar to that of the normal proton; and the mirror electron mass is perhaps ten to 100 times heavier than that of the normal electron, while the value of mirror electric charge is the same as for normal matter.

In Berezhiani et al. (1995), the possibility was raised that mirror matter might be detected by lensing or other gravitational phenomena, based on the mirror structures that might form, such as supermassive mirror black holes, mirror machos, etc. The purpose of this paper is to study specifically the formation of mirror structures in this model so as to permit more detailed investigation of their implications for the model.

The question of initial condensation and star formation of the primordial hydrogen cloud of the familiar universe has been a subject of discussion among cosmologists for the obvious reason of understanding the origin of first stars and galaxies (see for example, Peebles and Dicke 1968; Silk 1977; Palla et al. 1984; Tegmark et al. 1996). Its study combines information from atomic physics and statistical physics as well as cosmology and chemistry. In our discussion, we take over the relevant ideas with appropriately scaled atomic parameters and combine them with the cosmology of the hidden mirror world to get a qualitative understanding of structure formation in the (exclusively hydrogen) mirror sector. A significant difference is that, whereas

dust particles play a major role in understanding most of the detailed structure in the familiar sector, the mirror sector for the range of interest of the $\zeta \equiv m_{\tilde{e}}/m_e$ parameter is devoid of any nuclei heavier than the hydrogen and is thus free of dust particles. This to an extent simplifies our discussion and enables us to draw the conclusions that we do. Of particular interest to us is the nature and evolution of the low mass Population III stars for the visible universe. Our calculations draw from the literature on Population III stars, particularly the classic 1968 paper of Peebles and Dicke.

The plan of the paper is as follows. In Section II, we review the necessary elements of the weak scale asymmetric mirror model (WSAM). In Section III, we address cosmological structure issues, including mirror recombination, primordial hydrogen molecule formation and the mirror Jeans mass. It is not surprising that, because of the similarity in proton mass, the mirror matter Jeans mass at matter domination is about that of a globular cluster; an important difference is that because of the greater electron mass, mirror matter recombination precedes both that of normal matter and the point of matter domination over radiation. In Section IV we address the fate of Jeans mass "mirror globs." We find that for most regions of parameter space, the energy loss rate should be sufficient to support considerable condensation. We show that, as ζ increases, molecular cooling becomes ineffective but cooling by the hyperfine structure transition seems to take over sufficiently rapidly as to leave in all probability no interesting ζ region without a cooling mechanism. In particular, we show that the rate of hyperfine cooling is small compared to the free fall rate. In Section V we discuss the fate of the globs, including possible scenarios within the context of the results of Sections III and IV and possible observational constraints.

II. Review of the Weak Scale Asymmetric Mirror Model

There exist several experimental indications of non-zero neutrino masses and mixings: these include (i) the solar neutrino deficits observed now in four different experiments, (ii) deficit of atmospheric neutrinos observed in IMB, Kamiokande and Soudan II experiments and (iii) a preliminary indication of direct accelerator neutrino oscillation from the LSND experiment (for a recent review, see Winter 1995). If all these data are confirmed by the planned experiments such as SNO, Borexino and Super Kamiokande as well as the new runs at LSND etc, they will have profound implications for the neutrino mass matrices as well as for physics beyond the standard model. One simple way to understand all these observations is to assume that there exists a fourth ultralight neutrino species beyond the three already known (Caldwell and Mohapatra 1993; Peltoniemi and Valle 1993) i.e. ν_e , ν_μ and ν_τ ; in this picture, the solar neutrino puzzle is understood via the oscillations

between the ν_e and the extra neutrino (denoted by ν'_e) both of these are assumed to have mass in the milli-eV range. The atmospheric neutrino puzzle is solved via ν_μ - ν_τ oscillation. The present indications from LSND experiment then imply that $m_{\nu_\mu} \simeq m_{\nu_\tau} \simeq \text{few eV}$. Indeed there exist analysis (Primack et al 1994) of the existing data on structure in the universe which seem to require a hot dark matter component at the level of 20% of the critical density which is fulfilled if the more massive of the neutrinos above have a mass of 2.4 eV each.

The problem with such a picture is that since LEP data implies that only three neutrino species can couple to the Z-boson, the fourth neutrino must be singlet (or neutral) with respect to the standard model gauge group. Since a standard model singlet fermion can in principle acquire an arbitrary mass in the absence of any symmetry protecting its lightness, the puzzle arises as to why such a neutrino (i.e. ν'_e) is so light. It was suggested (Berezghiani and Mohapatra 1995; Foot and Volkas 1995) that if there is a mirror sector of the universe with identical gauge structure and particle content to the standard model but decoupled from the standard model particles except thru gravity, then the same symmetry (i.e. $B - L$) that keeps the ordinary neutrinos massless (or light) will have an analog in the mirror sector (to be called $B' - L'$) which will keep the ν'_e also massless or ultralight. It was suggested (Berezghiani and Mohapatra 1995) that the lightest neutrino masses arise from Planck scale effects, in which case the masses of ν_e and ν'_e scale like the square of the weak scales in their respective universes (i.e. v_{wk}^2 and $v_{wk}'^2$) whereas their mixing goes like $v_{wk}'/v_{wk} \equiv \zeta$. From the MSW solution to the solar neutrino puzzle, one can then conclude that $\zeta \approx 30$. In this picture, the mirror analogs of ν_μ and ν_τ will have masses in the range of few KeV's so that they can constitute warm dark matter for the universe.

It furthermore turns out that since the value of Λ_{QCD} in the mirror sector is near that in the normal sector whereas the mirror down quark, d' is ζ times heavier than the d -quark, we expect $m_{n'} - m_n \gg \text{binding energy of nuclei}$. As a result, the mirror neutron whether bound or free is always unstable (Berezghiani, Dolgov and Mohapatra 1995) resulting in the startling conclusion that in the mirror sector the only stable atom is the mirror hydrogen atom (H'). The weak scale asymmetry model (WSAM) has also the major difference that the ionization energy of H' is perhaps on the order of 400 eV (for $\zeta = 30$).

The basic WSAM picture of the evolution of the mirror sector after the big bang has been discussed in Berezghiani, Dolgov and Mohapatra (1995) It was pointed out there that consistency with standard big bang nucleosynthesis requires that there be asymmetric reheating after inflation in the two universes with $T \simeq T'/2$. In fact, in Berezghiani, Dolgov and Mohapatra (1995) we constructed realistic models where the asymmetric inflationary reheating is intimately connected with the asymmetry in

the electroweak scales. The rest of the history of the mirror sector can be worked out until recombination in the mirror sector which takes place when the temperature of the universe is around few tens of eV due to higher ionization energy of the mirror hydrogen. The nature of structure in the mirror sector depends on the detailed dynamics of the mirror sector and is the problem we attempt to tackle in this paper.

III. The Early Years

In attempting to study possible structure formation in the mirror universe in WSAM, we follow a scenario similar to the familiar sector (Kolb and Turner 1990; Weinberg 1972; Peebles 1993 and references therein). For ζ mildly greater than one ($\zeta \geq 3$), mirror recombination takes place before matter dominance. After the mirror recombination (at which point the mirror baryon component dominates the expression for Jeans length), the mirror universe contains a neutral hydrogen cloud with a small fraction of ionized hydrogen and electrons. When the universe later becomes matter dominated, the density fluctuations grow with time until the expansion of the high density regions stop and violent relaxation takes place leading to isolated "globbs". The future evolution of the globbs is dictated by the rates for physical and chemical reactions that determine the extent of energy loss by the globbs. If the energy loss rate is significant, then condensation to jupiter type objects of low mass or supermassive black holes can proceed; otherwise the gas cloud remains diffuse making detection difficult. The primary difference between the mirror and the familiar sector will be the scale factor ζ which will make the reaction rates in the mirror universe different.

We compute: (1) amount of ionization at mirror matter recombination; (2) density of primordial mirror hydrogen molecules; (3) Jeans mass and length of a mirror matter "glob" at matter domination; and (4) glob parameters after violent relaxation. We consider, for definiteness in most places, that the universe has the critical density, with normal and mirror baryons each providing 0.05 and mirror neutrinos, the model's warm dark matter, the remainder. We take the Hubble constant to be 50 km/s-Mpc. We take the ratio of the mirror proton mass to that of the normal proton to be $\alpha = 1.5$ and the ratio of the mirror temperature to the normal temperature to be $\beta = 1/2$. We sometimes keep the ratio of the mirror electron mass to that of the normal electron a free parameter ζ ; where a definite value is useful, we choose $\zeta = 30$.

In computing recombination in the mirror model, we follow the treatment of Kolb and Turner (1990) for normal matter, and reproduce it in order to compare the mirror matter calculation with it. We consider the reaction:

We define the variable $x = B/(2T)$, where B is 13.6 eV. The reaction rate for (1) is then given by:

$$\langle \sigma v \rangle = A_1 \left(x^{1/2} / m_e^2 \right) \quad (2)$$

with $A_1 = \frac{4\pi^2 \alpha^2}{\sqrt{3}} \equiv 1.46 \times 10^{-14} \text{ cm}^3 \text{ s}^{-1} \text{ MeV}^2$. We have for the equilibrium ionization fraction,

$$X_{eq} = 0.51 \eta^{-1/2} \left(\frac{m_e}{T} \right)^{3/4} e^{-x} \quad (3)$$

$$= A_2 x^{3/4} e^{-x} / (\Omega_B^{1/2} h) \quad (4)$$

with $\eta = (\Omega_B h^2) 2.68 \times 10^{-8}$ and $A_2 = 1.41 \times 10^7$. We have for the density of electrons,

$$n_e = \eta n_\gamma X_e = A_3 x^{-9/4} m^3 e^{-x} (\Omega_B h^2)^{1/2} \quad (5)$$

with $A_3 = 2.8 \times 10^{16} \text{ cm}^{-3} \text{ MeV}^{-3}$. Finally, the time of recombination is

$$t_R = \frac{2}{3} H_0^{-1} (T_0/T)^{3/2} = A_4 x^{3/2} / (h m^{3/2}) \quad (6)$$

with $A_4 = 1.55 \times 10^{10} \text{ MeV}^{3/2} \text{ s}$.

Setting $\langle \sigma v \rangle n_e t_R = 1$ to find the time at which freezeout occurs gives the condition,

$$A_1 A_3 A_4 m^{-1/2} x^{-1/4} e^{-x} \Omega_B^{1/2} = 1 \quad (7)$$

Using this one finds, $x^{-1/4} e^{-x} = 1.56 \times 10^{-13} \left(\frac{m}{\Omega_B} \right)^{1/2}$. This gives for the fraction f_e of free electrons

$$f_e = X_{eq} = \frac{A_2 m^{1/2} x}{[A_1 A_3 A_4 \Omega_B h]} = 6 \times 10^{-5} \frac{m}{\Omega_B h} \left(\frac{x}{27.5} \right) \quad (8)$$

This is in rough agreement with Kolb and Turner (1990).

In the WSAM model, we must modify reaction rates appropriately. Denoting all parameters of the mirror sector by a tilde and defining $\alpha = m_{\tilde{p}}/m_p$ and $\beta = \tilde{T}/T$ and $\zeta = \frac{m_{\tilde{e}}}{m_e}$ as before, we have for the reaction rate for the analog of reaction (1)

$$\langle \sigma v \rangle = A_1 \tilde{x}^{1/2} / \tilde{m}_e^2 \quad (9)$$

where we have assumed that the cross section for (1) scales with the square of the Bohr radius and $\tilde{x} = \tilde{B}/2\tilde{t}$. The analogues to Equations (3-6) are

$$\tilde{X}_{eq} = A_2 \alpha^{1/2} \tilde{x}^{3/4} e^{-\tilde{x}} / (\Omega_{\tilde{B}}^{1/2} h) \quad (10)$$

$$\tilde{n}_e = A_3 \tilde{x}^{-9/4} \tilde{m}^3 e^{-\tilde{x}} (\Omega_{\tilde{B}}^{1/2} h) / \alpha^{1/2} \quad (11)$$

$$t_{\tilde{R}} = A_5 h^{-1} \left(\frac{\tilde{x} \beta}{\tilde{m}} \right)^2 \quad (12)$$

where $A_5 = 9.6 \times 10^9 \text{ MeV}^2 \text{ s}$. Setting $1 = \langle \tilde{\sigma} \tilde{v} \rangle \tilde{n}_e t_{\tilde{R}}$ gives

$$\tilde{x}^{1/4} e^{-\tilde{x}} = \left(\frac{\tilde{m} \alpha^{1/2}}{\Omega_{\tilde{B}}^{1/2} [A_1 A_3 A_5 h \beta^2]} \right) \quad (13)$$

so that we have

$$\tilde{X}_{\tilde{R}} / X_R = (A_4 / A_5) \left(\frac{m^{1/2} \tilde{x}^{1/2}}{x} \right) (\zeta \alpha / \beta^2 h) \simeq 2.5 \zeta \quad (14)$$

Numerically, Eq(14) corresponds, with our standard parameters ($\zeta = 30$, etc), to about 10% unrecombined mirror electrons.

We now use this result to compute primordial formation of mirror matter molecules (Hydrogen). Primordial molecule formation has been addressed in detail by Lepp and Shull (1984) and in summary by Peebles (1993) H_2 is formed in the early universe, before galaxy formation, principally in two catalytic processes

followed by

and

followed by

In each case, the first reaction is slow and the second fast. In each case, the amount of H_2 formed is determined by the temperature at which the CBR can no longer dissociate the ion (H^- or H_2^+). Lepp and Shull give the two temperatures as $2.75Kz_{eff}$ with $z_{eff}=64$ and 190 , for H^- and H_2^+ , respectively; the corresponding binding energies are 0.75 eV and 2.65 eV. The amount of H_2 produced, in either case, is then

$$f_2 = t(z_{eff}) \frac{df_2}{dt} = \langle \sigma v \rangle (z_{eff}) n_H(z_{eff}) f_e t(z_{eff}) \quad (19)$$

where t is the age of the universe at z_{eff} . f_2 in Eq (19) rises with z_{eff} since the z^3 behavior of n_H outweighs the $z^{-3/2}$ behavior of $t(z_{eff})$. For familiar H_2 , Lepp and Shull show that, although z_{eff} is larger for Eq (19), the contribution of Eq (15) is about three times as big owing (mostly) to the smaller velocity of the proton in Eq (17). For mirror matter, however, the velocity of the electron falls like $\zeta^{-1/2}$, so we expect Eq (19) to be a good approximation and dominant for $\zeta \geq 9$. $\langle \sigma v \rangle$ for familiar matter, for Eq (19) is a constant ($1.4 \times 10^{-18} cm^3 s^{-1}$ is used by Lepp and Shull (1984)) at low energy, so a conservative estimate for mirror matter is simply to scale it as ζ^{-2} . z_{eff} scales as ζ/β since $\tilde{T} = \beta T$, so we take $z_{eff} = 380\zeta$. Thus, for mirror matter, Eq (17) becomes

$$\tilde{f}_2 = \tilde{f}_e \langle \tilde{\sigma} \tilde{v} \rangle n_{\tilde{H}}(z_{eff}) t(z_{eff}) \quad (20)$$

with $\tilde{f}_e = 4 \times 10^{-3}\zeta$ and $t(z) = 4 \times 10^{17}/z^{3/2}$, giving

$$\tilde{f}_2 = 1.2 \times 10^{-6} \zeta^{1/2} \quad (21)$$

This is about 60 times the amount for familiar matter, with the same Ω , for this process. It would be of interest to compare this rate with results for muonic molecules; however the reactions of interest for muon catalysis appear to be only those involving atoms, rather than ions, since densities are high (Hughes and Wu 1977). On the other hand, the precise numerical result in Eq (19) will not be needed below. In Section IV, we will note that the most important factor in molecular cooling, as a function of zeta, is that, for given zeta, the temperature be high enough to permit exciting molecules out of the rotational ground state.

Third, we turn to the Jeans mass. We consider, as noted, a three component system - massive mirror neutrinos dominating the mass density, together with both

normal and mirror baryons. The "baseline value" for matter domination is $z=5800$; and the eigenvalue Jeans equation is (Kolb and Turner, 1990)

$$\delta_i v_i^2 k^2 - 4\pi G_N \Sigma_j \rho_j \delta_j = 0 \quad (22)$$

where δ_i are the density fluctuations in the various components, ($i = \tilde{\nu}, \tilde{B}, B$) ρ_i are the mean densities, v_i are the sound velocities in the different media and k is the wave number for the density fluctuation. The various velocities are given by $v_{\tilde{\nu}} = \sqrt{3\tilde{T}/m_{\tilde{\nu}}}$, $v_{\tilde{B}} = \sqrt{3\tilde{T}/(m_{\tilde{B}}\tilde{T}_{rec})^{1/2}}$, $v_B^s = 1/\sqrt{3}$

The solution to Eq (22) is

$$\delta_i = A/v_i^2; \quad k^2 = 4\pi G_N \Sigma_j \rho_j / v_j^2 \equiv \left(\frac{2\pi}{\lambda}\right)^2 \quad (23)$$

We note that the other eigenvalues of Eq. (22) are all zero, for any number of components, and that the amplitudes in the solution of Eq. (23) are driven by the inverse of the sound speeds; the densities do not enter. The evolution of galaxies presumably proceeds at leisure as in warm mixed dark matter models; see, for example, Colombi, Dodelson and Widrow (1996) and references therein for recent detailed discussion. It is clear that, as the coolest component by far, the mirror baryons dominate the solution. We find a Jeans length and mass of

$$\lambda_J \simeq 7 \times 10^{18} (z_6/z_{MD})^{1/2} \tilde{\Omega}_J^{-1/2} \text{ cm} \quad (24)$$

$$M_J = 2.9 \times 10^{38} \tilde{\Omega}_J^{-1/2} (z_{MD}/z_6)^{3/2} \quad (25)$$

where $z_6 = 5.6 \times 10^3$ and $\tilde{\Omega}_J = \Omega_{\tilde{B}}/0.05$ The mass in Eq. (25) is solely that of the mirror baryons within the Jeans length. The basic result is, not surprisingly, on the order of a globular cluster. In Table 1, we collect some of the features of the early thermal history.

Finally, we need to make assumptions about the rate of growth of the inhomogeneity. We adopt a simple parametrization. We assume that the mirror hydrogen globular cluster size glob continues to expand with the rest of the universe from the time at $z=5800$ of initiation of matter domination until

$$z_{stop} \equiv 5800 z_M \quad (26)$$

At that point "violent relaxation" begins. It leads to glob of half the original(z_{stop}) size with temperature determined by the virial theorem. The Mass, radius, Temperature, and mirror particle density in the glob, and the age of the universe are given, in terms of the parameter z_M , in Table 2. There will, of course, be a distribution in mass of the structures; we restrict this first look at the structure question to just those of approximately the Jeans mass.

The prediction of the mirror matter model is then formation of structures roughly on the order of those shown in Table 2. There is a strong dependence on the choice of the parameter z_M in the table. We, of course, do not know the rate at which inhomogeneities in mirror matter will grow, but we do know that they should become nonlinear earlier than those of normal matter, since mirror recombination is earlier (and indeed before the time of matter domination) and since δ_i in Eq (23) is significantly larger because of the smaller sound velocity. In the estimates below, we shall consider 0.1 and 0.01 values that can't be ruled out for z_M , but not necessarily maximum and minimum values.

IV. Energy Loss

In this section we estimate rates at which the mirror matter globs can lose energy by different processes so as to determine how compact present day objects might be in order to estimate their susceptibility to gravitational detection. We consider three processes: (1) free-free radiation – as modified by continuing recombination; (2) the atomic mirror hydrogen hyperfine structure line (or 7 mm line); and (3) the ortho-para mirror molecular rotational transition line. The basic tension in cooling is that the temperature scale is set by the time of matter domination and so is somewhat similar to that for normal matter; but the processes are all strongly dependent on the mirror electron mass which is greater by 10 to 100 than for normal matter. There is also strong dependence on the parameter z_M which, as seen in table 2 enters in most quantities of interest. We make estimates mostly on the basis of constant (average) densities, but consider where necessary modifications for an isothermal sphere. Note that, since in the mirror sector there is no stellar burning, there is in all likelihood no reionization and we do not consider such a possibility.

We begin with the question of glob recombination which will determine the availability of mirror electrons for free-free radiation. Using Eq (9), with T as in Table 2, we can write for the time rate of change of the mirror electron fraction in the glob

$$\frac{df_e}{dt} = -n_H f_e^2 \langle \sigma v \rangle = -f_e^2 / t_q \quad (27)$$

where $t_q \simeq 10^{10} z_M^{-5/2}$ sec. The solution is

$$f_e = f_{e,0}/[1 + t f_{e,0}/t_q] \quad (28)$$

We thus see that free electrons will be reduced by at least a factor of ten in time t_0 , the current age of the universe, so long as z_M is greater than 0.01, and considerably more for higher values. We note that the gammas from glob recombination do not constitute a thermal energy mechanism for the glob since the Thomson cross section is too small for them to heat the remaining electrons, so that they either remove binding energy from the glob in the case of recombination to excited states or reionize mirror atoms in the case of gammas from recombination to the 1S state too far from the glob surface.

The rate at which the electron gas can absorb energy T from an atom is given by

$$t_1^{-1} \simeq f_{\bar{e}} n_{\bar{H}} \tilde{\sigma} v_{\bar{e}} \left(\frac{m_{\bar{e}}}{m_{\bar{H}}} \right)^2 \simeq (\zeta/10)^{-1/2} 10^{-10} f_{\bar{e}} z_M^{7/2} \text{ sec}^{-1} \quad (29)$$

where we have estimated the cross section as being just the mirror bohr area, Eq. (27) assumes that there is no problem with radiating the energy; it just computes the time needed to transfer the energy from an atom to the free electrons (in fact the bremsstrahlung rate will fall as ζ increases). The result is that, although fewer scatterings are needed as zeta increases, the cross section falls so that the time required is nearly independent of zeta. Note that the factor of $(m_{\bar{e}}/m_{\bar{H}})^2$ represents the random walk in energy space needed. The actual rate of energy loss will be still less because of opacity, but Eq (29) shows, taking into account the decrease in $f_{\bar{e}}$ of Eq (28) as z_M increases from 0.01, that significant condensation via free-free radiation must take more than the age of the universe. Note that, since we have $\sigma \approx \zeta^{-2}$, $f_{\bar{e}} \approx \zeta$, $v \approx \zeta^{-1/2}$ in Eq.(29), this conclusion is independent of ζ . This argument also indicates that Compton cooling (scattering of electrons off CBR photons)(see Silk,1976) cannot cool either in the parameter range under consideration.

Next, we turn to a particularly interesting possibility, open to mirror hydrogen because of the increased energy per transition and the increased transition rate that come with the greater electron mass– the atomic hyperfine transition. The time needed to radiate an atom's total kinetic energy in units of the hyperfine transition energy is given by

$$t_{2,R} \simeq \left(\frac{3/2T}{\epsilon_{HF}^N \zeta^2} \right) \left(\frac{t_{HF}^N}{\zeta} \right) \simeq 10^{21} z_M / \zeta^3 \text{ sec} \quad (30)$$

where the factor in the first set of parentheses is the number of transitions each atom needs to make, while ϵ_{HF}^N and t_{HF}^N are the energy and inverse radiation rate for the case of normal matter. Here we have used the fact that the hyperfine splitting goes like m_e^2/m_N . We can derive a second characteristic time in addition to that of Eq.(30) which is the total time required for the atoms to make the transitions that radiate away their kinetic energy. The second characteristic time is that required to excite the atoms to the higher energy state so that they can do the radiating. The reason for treating the two times separately is that each must be less than the age of the universe in order for the glob to cool by this process. The total excitation time is given by

$$t_{2,E} \simeq \left(\frac{3/2T}{\epsilon_{HF}^N \zeta^2} \right) (n_{\tilde{H}} \sigma_{\tilde{H}\tilde{H}} v_{\tilde{H}})^{-1} \simeq 10^{10} z_M^{-5/2} sec \quad (31)$$

In Eq. (31), we have taken the cross-section to be six Bohr areas (Allison and Delgarno 1969). We see from Eq (30) that energy loss from the glob, in less than the age of the universe, tends to be possible for small values of z_M and large values of ζ that is, when the kinetic energy to be dissipated is small and the energy dissipated per transition is large. We note, however, that our calculation is a simple-minded one; we have not considered such possible additional effects as collisional de-excitation. We note that for $\zeta > 1000$, the energy difference between the two levels would increase to the eV range thereby making it difficult to excite the atom to the higher level (i.e. making $t_{2,E}$ larger), thus disfavoring this as a cooling mechanism.

Finally, we turn to cooling by molecular radiation. This is the chief source of cooling in the Population III globular cluster work, for example of Peebles and Dicke (1968) and Tegmark et al. (1996). In the present case its effectiveness is enhanced (for $\zeta > 1$) by the increased energy carried away in each transition, but is decreased by the difficulty of exciting rotational states, since even the lowest-energy excited state soon becomes more than the temperature that corresponds to $z_M = 0.1$. We can write for the time needed to remove energy $3T/2$ from every atom

$$t_3^{-1} \simeq \Lambda_2 \langle \sigma v \rangle f_2 \left(\frac{\Delta E}{3/2T} \right) \simeq 7 \times 10^{-11} \zeta^{1/2} z_M^{5/2} \Lambda_2 sec^{-1} \quad (32)$$

where we use again the bohr area for σ , use f_2 as computed in Section II, and have $0.015eV\zeta^2$ for ΔE using the experimental value for the ortho-para transition for $\zeta = 1$. The lowest excitation energy is three times the size of the "average" rotational energy $((m_e/m_H)E_{el})$; characteristic energy levels are given in Table 3.

The factor Λ_2 takes account of the fraction of collisions that are sufficiently energetic to excite the $J=0$ to $J=1$, para to ortho, hydrogen molecule transition, and is given by

$$\Lambda_2 = \frac{\int d^3v_1 d^3v_2 e^{-(2mv_1^2 + mv_2^2)/2T} \theta(m/3(v_1 - v_2)^2 - \Delta E)}{\int d^3v_1 d^3v_2 e^{-(2mv_1^2 + mv_2^2)/2T}} \quad (33)$$

Eq. (33) is written for collisions of H atoms with H_2 molecules (hence the factor of 2 in the exponent); however Λ_2 is independent of the masses of the particles and depends only on $\Delta E/T$. Evaluating Eq.(33) numerically, we find, approximately, that the time in Eq.(32) is greater than the age of the universe for the curve $t_3 = t_0$ in Fig.1. That is, the glob can lose energy by molecular radiation for larger values of z_M and smaller values of ζ , since in this case it is the ability to excite that is important. The range of ζ for which molecular radiation can be effective will be further limited by the decreasing (with ζ) cross-section for collision induced radiation but it will not be necessary to compute this additional effect nor do we compute the extra time needed to excite to $J = 2$ state so that radiative quadrupole radiation can occur without collision.

We now consider the question of opacity. For the case of the rotational line, following Lang (1980) and Rohlfs (1986), we have for the opacity.

$$\kappa_\nu = \frac{c^2}{8\pi\nu^2} f_2 n_H A [1 - e^{-\nu/T}] \phi(\nu) \simeq 3 \times 10^{-18} n_H / z_M^{1/2} \quad (34)$$

where A and ϕ are given by

$$A = \frac{32\pi^4}{3c^2} \alpha \nu^3 a_B^2 / \zeta^2 \quad (35)$$

and

$$\phi(\nu) = \frac{c}{2\nu} \left(\frac{M}{2T \ln 2} \right)^{1/2} \simeq 10^4 / z^{1/2} \nu \quad (36)$$

From Eq (34) one can check that 90% of the mass is within an optical depth of 300 from the surface so that total radiation time does not become a limiting factor in energy loss. One can also see from Eq (35) that, for the case of the magnetic dipole

hyperfine structure line the opacity will be reduced by at least a factor of 10^5 so that the optical depth will be less than one.

We have found that: (i) free-free radiation cannot give enough energy loss to permit collapse for any ζ , for reasonable z_M ; (ii) hyperfine structure radiation cannot give such energy loss if ζ is too low, for reasonable z_M because the rate at which energy is radiated is too small and it cannot give such energy loss if ζ is too high (over 1000), for reasonable z_M , because the rate at which the upper hyperfine state is excited becomes too small; and, (iii) finally, molecular radiation cannot give such energy loss if ζ is too high (over 5), because the ortho to para molecular transition cannot be excited with the available thermal kinetic energy. These results are summarized in Figure 1 where we show the three curves

$$t_{2,R} \equiv 10^{21} z_M / \zeta^3 = t_0 \equiv 4 \times 10^{17} \text{ sec} \quad (37)$$

$$t_{2,E} = 10^{10} z_M^{-5/2} / \Lambda_1 = t_0 \quad (38)$$

where Λ_1 is the analogue of Eq.(33) for $\tilde{H}\tilde{H}$ scattering. Finally, the condition $t_3 = t_0$ leads to

$$z_M^{5/2} \Lambda_2 = 1.2 \times 10^{-8} \quad (39)$$

In Fig 1, the curve left-most at the bottom ($t_3 = t_0$) is that above which the glob can cool by means of the ortho-para H_2 transition; below it, the temperature of the glob after violent relaxation is too low to excite the transition. The second curve ($t_{2,R} = t_0$) is that below which the glob can radiate away its energy by means of the hyperfine transition; above it, too many transitions are needed to radiate away the thermal energy in time t_0 . The rightmost curve is that above which the glob can excite atoms to the upper hyperfine state a sufficient number of times to radiate away the thermal energy; below it the density and excitation rate are too low. In the shaded area between the first two curves and under the third curve cooling cannot take place. Our result is that cooling is likely possible for most of the region $\zeta \leq 400$ and $z_M \geq 0.01$ with the lower bound on $\log z_M$ rising approximately like $1.6 \log \zeta$.

V. Where Are They Now?

Given the above results, we can now ask the likely fates of mirror globs and the possibilities for detecting signs of their existence. There are three broad possibilities: (i) Puffy Globs; this would be the case if we are in a region of the $z_M - \zeta$ plane in which the globs cannot lose energy within t_0 . (ii) Cluster Globs; this would be the case for a region of the $z_M - \zeta$ plane in which the globs can lose energy sufficiently

rapidly, and there is fragmentation to low mass bodies, which would essentially be white dwarfs or "small" black holes, since no nuclear burning is possible. (iii) Black Globbs; this would be the case for a region of the $z_M - \zeta$ plane in which there is energy loss and no fragmentation, and hence collapse to a supermassive black hole.

Case (i) will obtain for the shaded regions of Figure 1, providing there are not important energy loss mechanisms we have neglected. Case (ii), in principle, could obtain for portions of the $z_M - \zeta$ plane in which the energy loss is through the hyperfine line. This is because the glob will be optically thin to the hyperfine line and hence, if the energy loss were rapid enough, particle velocities will decrease and regions of smaller Jeans length will appear. See, for example, the discussion of Bohm-Vitense (1989), or the original paper of Hayashi (1966). However, the rate of energy loss is never rapid enough from the hyperfine line. That is, we can take the total time for energy loss by adding Eqs. (37) and (38), divide by the free fall time, $(G\rho)^{-1/2}$, and minimize the ratio with respect to ζ . We find

$$(t_{2R} + t_{2E})/t_{ff} \geq 10 \quad (40)$$

Were the left hand side of Eq. 40 much less than one, we could expect fragmentation through decreasing Jeans mass leading to subregion collapse. Case (ii) will also obtain if the mechanism of Peebles and Dicke (1968) for sequential central star formation in globular clusters (followed by glob reheating and radiation from central objects formed) is applicable, or if other energy loss mechanisms turn out to be important. The mechanism of Peebles and Dicke might maintain case (i) for the current age of the universe. Knowledge of star formation, for ordinary matter, especially formation of Population III stars, is not sufficiently advanced, as far as we can determine, to draw any confident conclusions. Case (iii) will, of course, obtain where there is energy loss without fragmentation to case (ii).

Given these three cases, we can look a little further into the fate of the globbs by asking about glob-glob scattering under the assumption that the globbs are bound to galaxies. We take a simple model of our galaxy as a sphere of radius 70 kpc, with a virial velocity on the order of $v_g = 10^{-3}c$. The number of collisions a glob is likely to make is then given by

$$N_c = (N_g/V_g)\sigma_g v_g t_0 \approx 10^{-3} z_M^{-2} \quad (41)$$

where we have assumed $N_g = 10^6$ globbs in the galaxy, and taken as the cross section the area corresponding to the glob radius in Table 2. We have neglected gravitational focusing. We can, in addition, ask about the angle of scattering. We have (see, for example, Binney and Tremaine 1989)

$$\tan\theta \approx \Delta v/v = 2GM/(bv^2) \approx 0.1 z_M \quad (42)$$

The results of Eqs. (39) and (40) are that we are near a borderline; we might have a lot of scattering, including some large angle scattering that could liberate the glob from the galaxy. It would appear unlikely that we would have less than on the order of a percent of the globs liberated. Thus, one might consider searches for shadow matter globs both inside the galaxy and outside. Searches inside benefit from the possible existence of a large number of globs close at hand. Searches outside benefit from the large ratio of globs to galaxies, even with only 1% liberation.

We note that we would expect, in case (ii) above that some percentage of the cluster elements would be liberated in glob-glob scattering, but we would consider it unlikely that a large fraction of mirror matter goes into making MACHOs. We should also note that cases (i) - (iii) above are not necessarily mutually exclusive: while there will only be one value of ζ , we expect some range of values of z_M for globs. If near a border, these could include more than one case in the above taxonomy. Finally glob-glob mergers could play an important role in determining some mirror sector structures and should be considered in more detail.

Finally, we turn to the question of potential observational constraints. The one that comes most immediately to mind is that of lensing, galactic and extragalactic; detailed analysis is needed and possible based on the above results, but is beyond the scope of the present paper. There are, in addition, other possibilities. One interesting way to limit the number of globs that could be resident in the galaxy is through the study of wide angle binary star systems. These would be disrupted by close enough passage of massive mirror globs in the same way they are disrupted by passage of giant molecular clouds as discussed by Bahcall, Hut and Tremaine (1984). There is similar application by Hut and Tremaine (1985) to the question of loss of the sun's Oort cloud, the source of (long-period) comets. Applying the results of Bahcall, Hut and Tremaine, we find a time for (tidal) disruption of wide angle binary systems by mirror globs somewhat less than the age of the galaxy. However, as emphasized by Weinberg (1985) in addition to the uncertainties in our model, there is the problem of not knowing the initial numbers of wide angle binaries with enough confidence to say how many have been disrupted. We therefore do not consider this a reliable test of the model. We note in passing that there is a bound (Anderson et al. 1995) on how much nonluminous matter, including mirror matter is allowed to exist around the sun.

Another fruitful area for detecting mirror globs would be work on limiting the number of halo black holes the galaxy can have, including observational work such as searching for X-rays from infalling matter. With 10^6 globs in the galaxy, there should be considerable contribution to the X-ray background. In a separate, straightforward direction, the above rough model of the galaxy with a million globs in a 70 kpc sphere would have more than one glob within 1000 pc of the sun. One

might be able to look at peculiar motions of stars within such a distance to see whether they are consistent with a large, but unseen, nearby mass.

There would be other gravitational effects on galaxies from mirror globs. Rix and Lake (1993), consider limits on $10^6 M_\odot$ objects. They show that such objects could contribute to dark matter for the Milky Way but that $10^3 M_\odot$ is the maximum allowed by relaxational disk heating in two spiral dwarf galaxies. They point out that this result would not hold for objects that could be dissipated in the higher rate of collision for the dwarf case. Their result argues against black compact globs but not against the other cases. It probably does not rule out case (iii), since glob-glob scattering might in the dense environment of the dwarf galaxy, evade the constraint by the liberation from the galaxy of globs and by evaporation from the globs of some of their mirror hydrogen before collapse.

VI. Conclusion

We have analysed the cooling mechanisms for a Jeans mass glob in the mirror sector as a function of the two free parameters ζ and z_M which respectively denote the mass ratio of electrons in two sectors and the ratio of the redshifts at which the mirror globs undergo violent relaxation to that of matter domination. We found that for $5 \leq \zeta \leq 400$, cooling is likely to occur by means of the atomic hyperfine structure line. This overlaps with the range for ζ (between 10 to 100) required to understand the results of the solar neutrino observation. While we show that the dominant cooling mechanism in the ζ region of interest is too slow to give rise to glob fragmentation by itself, we cannot rule out with confidence any of the three end-point cases (at the current age of the universe) of: (i) puffy globs not greatly condensed, (ii) cluster glob with fragmentation to low mass bodies or (iii) black glob with collapse to a single black hole. We noted several possible ways to test and/or constrain the mirror idea and the three endpoints observationally including lensing, wide angle binaries, effect on relatively local stellar phase space distribution and black glob effects such as x-ray production.

Acknowledgments

One of us (VLT) very much appreciates the hospitality of the University of Maryland Physics Department, the assistance of the Lightner-Sams Foundation in acquiring the computer on which the numerical work was done and several helpful conversations with D. Rosenbaum who, inter alia, pointed out the work of Hut and Tremaine. We are both grateful to D. Armstrong, M. Blecher and M. Eckhause for discussion on muonic atoms, to E. Kolb and A. Bhatia for reading the early draft and especially to D. Spergel for several stimulating suggestions.
